Divorce Laws and Divorce Rate in the U.S.*

Stefania Marcassa[†]

Paris School of Economics

This Version: February 8, 2010

Abstract

At the end of the 1960s, the U.S. divorce laws underwent major changes and the divorce rate more than doubled in all of the states. The new laws introduced unilateral divorce in most of the states, and changes in divorce settlements, such as property division and child custody assignments in every state. Empirical literature has focused on the switch from consensual to unilateral divorce and found that this change cannot fully account for the increase in the divorce rate. What previous literature has ignored is other aspects of the legal change, and their effect on divorce rate in states where the decision remained consensual. In this paper I show that changes in divorce settlements provide economic incentives for both spouses to agree on divorcing. I solve and calibrate a model where agents differ by gender, and wages, and make marital status, investment, and labor supply decisions. Under the new financial settlements, divorced men gain from a favorable division of property, while women gain from an increase in joint child custody assignments. Since both of them are better off in the new divorce setting, the requirement of consent for divorce is not longer necessary. Results show that changes in divorce settlements account for

about 30% of the increase in the aggregate divorce rate. I also find that the increase in divorce rate of young couples with children contributes the most in the overall increase, and this is consistent with the data.

JEL Classification: J12, D13, K36

Keywords: Age-specific divorce rate, unilateral and consensual divorce, divorce laws, property division, alimony and child support, child custody.

1 Introduction

At the end of the 1960s, the U.S. divorce laws underwent major changes and the divorce rate increased from 12.0 divorces in 1960 to 25.0 divorces per thousand of married females in 1980. The reform introduced unilateral divorce law in most of the states and changes in divorce financial settlements in every state. The results of the empirical literature on the effects of the legal changes on the divorce rate are controversial, and focused on the switch from consensual to unilateral divorce. In particular, Friedberg, L. (1998) found that the switch to unilateral divorce accounts for 17% of the increase in divorce rate. Wolfers (2006) arrived at a different conclusion and found the increase in the divorce rate to be two-thirds the size of Friedberg, L. (1998)'s finding.

What previous literature ignored is the fact that the change in divorce rate occurred uniformly in all states regardless of whether the unilateral or consensual regime was adopted, and divorce financial settlements have been revised all across the U.S. The purpose of this paper is to evaluate the effect of the changes in financial settlements on the increase in the aggregate and age-specific divorce rate. The main changes in financial settlements include changes of property division rule, alimony and child support payments, child custody, and fathers' visitation rights. In particular, under the old fault-based law, the wife receives more than half of the community property. With the new no-fault law, community assets and liabilities are divided equally. Moreover, there have been changes in the amount of transfers from husbands to wives, especially when the mother has custody of the children. The rule that favorers the mother as the full custodial parent after divorce loses ground throughout the U.S. Today men and women have an equal right to custody in all states.

I provide a framework in which financial aspects of the legal change matter. In particular, I modify a standard dynamic life-cycle model of household behavior to include divorce settlements and analyze the effect of the legal changes on the couples' decisions of divorcing. In every period, married couples with and without children, decide whether or not to divorce. They cooperate when making decisions while

married, but do not cooperate as they get divorced. Divorce occurs when a new draw of match quality makes both better off single than married. One important feature of the model is that agents solve different problems depending on the lifecycle stage they are in. In particular, I divide the life-cycle into three parts: in the first part, agents make time allocation decisions about labor market, child care and leisure; in the second part, agents are childless and choose the amount of time to allocate between labor market and leisure; in the last period, all of the agents are retired. In every period they choose how much capital to accumulate. I calibrate the model to 1970 U.S. data and use it to simulate the impact of the legal reform on divorce rate of married couples of different ages.

I show that changes in divorce settlements create incentives for both spouses to agree on divorcing, neutralizing the difference between consensual and unilateral regime. Under the new regime, the gain from a favorable division of property for men offsets the loss of an increase child custody and child support payment requirements. Wives gain from an increase in liquidity coming from a higher percentage of husbands paying the alimony and child support transfer, and this offsets the loss from the new reallocation rule of property (up to a certain threshold of property to divide). The small increase in the number of father receiving sole or joint custody is not quantitatively relevant. Results show that changes in divorce settlements account for a substantial amount of the increase in the divorce rate in both the unilateral and the consensual regime. I also find that the increase in divorce rate of young couples contributes the most to the overall increase, and this is consistent with the data. This last result is driven by the division of life-cycle in the three parts. In the first part, married couples benefit from both of the divorce settlements changes, as parents provide for child care, and accumulate capital. In the second and third part of their lifetime, children are not living in the parental house anymore, and the legal reform affects the division of property and transfers to wives.

The rest of the paper is organized as follows. In the next section I document the pattern of divorced rate observed in the data, and empirical evidence of the changes in divorce settlements. Section 3 describes the model. Section 4 explains how the model is parameterized and calibrated, and presents results.

2 Empirical Evidence

From the end of the 1960s to the beginning of the 1980s, the divorce rate increased from 12 divorces to 23 divorces per thousands of married females of 15 years and older¹. Figure 1 shows the increase in divorce rate.

Figure 1: Divorce Rates per 1,000 of Married Females Source: National Center for Health Statistics, various years

This aggregate measure does not reveal age differences in the divorce rate, and it does assume a standardized age structure of women at risk. A more precise measure is given by the age-specific divorce rate, and data are shown in Figure 2. The data show that rates increased from 1970 to 1980 with the most dramatic increase occurring in the 20 to 44 age groups. The 50 and over groups show no relevant change in

¹The divorce rate is computed as the ratio between the total number of divorces in a particular year and the total number of married females that are 15 years and over in the same year.

this decade. In the Appendix I provide the details about the states included in the computation of the rate.

Figure 2: Age-Specific Divorce Rates per 1,000 of Married Females Source: National Center for Health Statistics

The increase in the divorce rate coincides with the introduction of the Uniform Marriage and Divorce Act promulgated in 1970. It introduced revolutionary changes in family law at a federal level².

Prior to the no-fault divorce revolution, a divorce could be obtained only through a showing of fault of one of the parties in a marriage. California was the first state to implement the no-fault ground divorce, and nowadays all of the states have eliminated fault as a ground for divorce. Not all of the states have yet introduced the unilateral

²The Uniform Marriage and Divorce Act was drafted by the National Conference of Commissioners on Uniform State Laws and by it approved and recommended for il all the states enactment in August 1970.

divorce regime: in seventeen³ out of fifty-one states both of the parties have to express their consents to divorce.

The legal reform also introduced changes about property division and child custody aiming to a more gender neutral legislation. In Section 307, *Disposition of Property*, we read:

"In a proceeding for dissolution of a marriage, legal separation, or disposition of property following a decree of dissolution of marriage or legal separation by a court [...], the court, without regard to marital misconduct, shall, [...], finally equitably apportion between the parties the property and assets belonging to either or both however and whenever acquired, and whether the title thereto is in the name of the husband or wife or both. [...]"

According to Weitzman (1985), in 1968 the wife who was usually declared as the "innocent" party, was awarded by more than half of the total property value. Data in table 1 shows that in only 12% of the cases the property was divided equally. Under the new law, the number of cases in which the property were equally divided increased substantially. By the end of the 1970s, the equal division became the norm⁴.

³The states that have not yet adopted the unilateral law are the following: Arkansas, District of Columbia, Illinois, Louisiana, Maryland, Mississippi, Missouri, New Jersey, New York, North Carolina, Ohio, Pennsylvania, South Carolina, Tennessee, Vermont, Virginia, and West Virginia.

⁴The average percentage of wealth inherited by the wife after divorce in sample data from the National Longitudinal Study (NLS) of the High School Class of 1972 (Fifth Follow-up, 1986) is about 58%.

Table 1: Division of Property in San Francisco County - Evidence from a random sample of court dockets. Source: Weitzman (1985)

Fraction of Property	1968	1972
Majority to Husband (over 60%)	2%	7%
Approx. Equal Division (40 to 60%)	12%	59%
Majority to Wife (over 60%)	86%	34%
Mean percentage to Wife	91%	62 %

Section 308 says the following on *Maintenance*:

"In a proceeding for dissolution of a marriage, legal separation, maintenance, or child support, the court, may order either or both parents owing a duty support to a child to pay an amount reasonable or necessary for his support, without regard to marital misconduct, after considering all relevant factors including:

- the financial resources of the child;
- the financial resources of the custodial parent;
- the standard of living the child would have enjoyed had the marriage not been dissolved;
- the physical and emotional condition of the child and his educational needs; and
- the financial resources and needs of the noncustodial parent."

U.S. Census data show that the realized amount of transfers from husband to wife changed from 1970 to 1980. In particular, women with children in the household⁵

⁵Note that the availability of data for that time period is restricted to cross sectional data. It is not possible to deduce whether divorced mothers are sole or joint custodian of the children present in the household at the time of the survey.

were more likely to receive the transfers. Table 2 shows the realized value of transfers from husbands to wives in 1968 an 1980, and the percentage of receivers. The value is computed as a percentage of total average labor income of a married man of age 20 to 39.

Table 2: Transfers to Wives as a Percentage of Young Married Men's Earnings Source: IPUMS 1968 and 1980

		1970	1980			
	Value	% Receivers	Value	% Receivers		
20-44	0.18	9.09	0.24	12.90		
45-59	0.32	5.78	0.27	6.53		
60+	0.18	14.75	0.36	5.73		

Table 3 shows the amount of alimony and child support as a percentage of a young married man by number of children 6 .

 $^{^6}$ In 1968, 20.10% of married couples of age 20 to 44 has no children; 20.74% has one child; 29.07% has two children; 16.35% has three children, and 13.74% has four or more children. There is no relevant change in the distribution of number of children from 1968 to 1980.

Table 3: Transfers to Mothers as a Percentage of Young Married Men's Earnings Source: IPUMS 1968 and 1980

		1980			
Children	Value	% Receivers	Value	% Receivers	
1	0.13	23.35	0.23	49.68	
2	0.20	38.94	0.34	52.65	
3	0.19	31.43	0.46	44.65	
4+	0.24	32.97	0.30	35.82	

Even thought changes in divorce law aimed to increase the gender (or parent) neutrality of child custody assignments, the observed percentage of sole custodian fathers did not substantially increase. Section 402 says about *Custody*:

"The court shall determine custody in accordance with the *best interest* of the child. [...]"

Table 4 shows the percentage of cases in which mothers and fathers obtained sole or joint custody for divorces occurred after 1968. See Appendix for details on the sample considered.

Table 4: Custody and Visitation Rights in 1986 Source: NLS of the High School Class of 1972 (Fifth Follow-up)

Mothers are sole custodians	90.2%
Fathers are sole custodians	3.2%
Joint custody	6.6%

3 The Model

In this section I develop a model of divorce decision in order to assess the quantitative contribution of the legal changes to the increase in age-specific (and aggregate) divorce rate in the U.S.

3.1 Environment

The economy is populated by four types of agents that differ by gender and marital status. Time is discrete, finite, and indexed by t = 0, 1, ..., T. Agents are alive for T periods and are ex-ante heterogenous. Specifically, married couples are indexed by a match quality $q \in \mathbb{R}$ that follows an idiosyncratic stochastic process. In every period married couples receive a shock on their match quality, choose their optimal allocations and decide whether to remain married or to divorce. Divorce requires consensual agreement. The timing of the model is shown in the following figure.

Figure 3: Time Line

There is not remarriage, and divorce is an absorbing state. Husband and wife cooperate when making decisions, but each agent behaves non cooperatively while divorced. That is, a divorced agent chooses its optimal allocations taking as given the optimal choices of the divorced partner. There is uncertainty in the quality of the match, and in the possibility of receiving alimony and child support transfers. Credit market are perfect and r denotes the net rate interest. To analyze the effect of the change in divorce law on agents at different stages of their life time, I divide the life cycle in three parts, as shown in Figure 4.

Figure 4: Life-cycle of Married Couples

Agents live for fifty years. They are born as married at age 20, and die for sure at the age of 75. Initial matching is exogenous. From age 20 to age 44 (i.e. in the first stage of their life cycle), married and divorced agents provide consumption for their children, and allocate time between market, leisure, and child care. From age 45 to age 59, all of the households are childless. Agents continue to work in the market. Finally, in the last part of their life cycle, agents retire and consume their savings. For the remaining of the paper, the subscripts f and f denotes female and male. In the following section, I describe the maximization problem that married and divorced agents solve at the different stages of their life cycle.

3.2 Married Couples

During the first part of their life cycle, agents allocate their time between market, child care, and leisure. I abstract from fertility decision and assume the number of

children to be exogenous. The dynamic program of married couples of age 20 to 44 is the following:

$$V_{M,1}(b_1, q_1) = \max_{\left\{c_1^i, c_1^k, l_1^i, t_1^i, h_1^i, b_2^i\right\}} \sum_{i=f, m} \gamma_i \left\{ \log c_1^i + \log c_1^k + \alpha_l \log l_1^i + \alpha_{tk}^i \log \left(t_1^f + t_1^m\right) \right\}$$

$$+ q_1 + \sum_{t=2,3} \beta^{t-1} E \left\{ \sum_{i=f, m} \gamma_i V_1^i \left(b_t^i, q_t\right) | q_{t-1} \right\}$$

$$s.t. \qquad c_1^f + c_1^m + c_1^k \le w_1^f h_1^f + w_1^m h_1^m + (1+r) b_1 - b_2$$

$$l_1^i + h_1^i + l_1^i = 1 \ \forall i = f, m$$

$$b_1 \ge 0 \text{ given}$$

Each agent i = f, m in the couple chooses consumption c_1^i , leisure l_1^i , total child care time t_1^i , market time h_1^i , and savings b_2 , to maximize the Pareto weighted sum of spouses' utility⁷. Note that children's consumption and total⁸ child care time $(t_1^f + t_1^m)$ are both public goods. Note that, while the utility weight on child's consumption is the same for both parents, I allow them to have different utility weights on the time spent with children. The wage rate is denoted by w_1^i for an agent i = f, m in period 1. Moreover, the value of being married depends on the random variable q that the couple draws at the beginning of every period. q_t is defined as follows:

$$q_t = q_0 + \epsilon_t$$

where ϵ_t follows a first-order autoregression:

$$\epsilon_t = (1 - \rho)\mu + \rho \epsilon_{t-1} + \varphi_t \text{ with } \varphi_t \sim N(0, \sigma_{\epsilon}^2) \text{ and } \epsilon_1 = 0$$

 $[\]frac{7}{2}\gamma_i$ is the Pareto weight on agent's i utility.

⁸More precisely, t_1^i is equal to time spent with one child times the number of children in the household.

If there are no children in the household, the couple solves the following problem:

$$V_{M,1}(b_{1}, q_{1}) = \max_{\left\{c_{1}^{i}, l_{1}^{i}, h_{1}^{i}, b_{2}^{i}\right\}} \sum_{i=f,m} \gamma_{i} \left\{\log c_{1}^{i} + \alpha_{l} \log l_{1}^{i}\right\}$$

$$+ \sum_{t=2,3} \beta^{t-1} E \left\{\sum_{i=f,m} \gamma_{i} V_{t}^{i} \left(b_{t}^{i}, q_{t}\right) | q_{t-1}\right\} + q_{1}$$

$$s.t. \qquad c_{1}^{f} + c_{1}^{m} \leq w_{1}^{f} h_{1}^{f} + w_{1}^{m} h_{1}^{m} + (1+r) b_{1} - b_{2}$$

$$l_{1}^{i} + h_{1}^{i} = 1 \ \forall i = f, m$$

$$b_{1} > 0 \text{ given}$$

In both cases the continuation value is defined as follows:

$$V_t^i\left(b_t^i, q_t\right) = \begin{cases} V_{M,t}^i\left(b_t, q_t\right) & \text{if } \mathbf{ONE} \text{ of the spouses wants to remain married} \\ V_t^{D,i}\left(xb_t\right) & \text{if } \mathbf{BOTH} \text{ of the spouses agree to divorce} \end{cases}$$

where $x \in [0, 1]$ is fraction of property inherited from marriage, and:

$$V_{M,\tau}^{i}\left(b_{\tau}^{i},q_{\tau}\right) = \log c_{\tau}^{i} + \log c_{\tau}^{k} + \alpha_{l} \log l_{\tau}^{i} + \alpha_{tk}^{i} \log \left(t_{\tau}^{f} + t_{\tau}^{m}\right) + \sum_{t>\tau} \beta^{t-1} E\left\{V_{t}^{i}\left(b_{t},q_{t}\right) | q_{t-1}\right\}$$

$$V_{D,\tau}^{i}\left(xb_{\tau}^{i}\right) = \log c_{\tau}^{i} + \log c_{\tau}^{k} + \alpha_{l} \log l_{\tau}^{i} + \alpha_{tk}^{i} \log \left(t_{\tau}^{f} + t_{\tau}^{m}\right) + \sum_{t>\tau} \beta^{t-1} E\left\{V_{D,t}^{i}\left(b_{t}\right)\right\}$$

$$(1)$$

where (1) is the value to agent i of being married with children in the household⁹. (2) is the value of being divorced and having full custody of the children. In the case in which either the couple had no children before divorcing or spouse i did not get joint or full custody, the value does not include utility from neither child's consumption nor child care time. See the next section for a more detailed description of the dynamic problem solved by divorced agents.

⁹If no children are in the household, the value does not include utility from child's consumption and child care time.

In the second part of their life cycle, married couples allocate their time between market, and leisure. At this stage children are not in the household, and parents do not receive any utility form spending time with them. The dynamic program of married couples of age 44 to 59 is the following:

$$V_{M,2}(b_2, q_2) = \max_{\left\{c_2^i, l_2^i, h_2^i, b_3^i\right\}} \sum_{i=f,m} \gamma_i \left\{ \log c_2^i + \alpha_l \log l_2^i \right\} + q_2$$

$$+ \sum_{t=3} \beta^{t-1} E \left\{ \sum_{i=f,m} \gamma_i V_t^i \left(b_t^i, q_t \right) | q_{t-1} \right\}$$

$$s.t. \qquad c_2^f + c_2^m \le w_2^f h_2^f + w_2^m h_2^m + (1+r) b_2 - b_3$$

$$l_2^i + h_2^i = 1 \ \forall i = f, m$$

where the continuation value is defined as above. In the third part of their life cycle, agents retire and consume their savings. The dynamic program of married couples of age 60 to 79 is the following:

$$V_{M,3}(b_3, q_3) = \max_{\{c_3^i, l_3^i, b_3^i\}} \sum_{i=f,m} \gamma_i \left\{ \log c_3^i + \alpha_l \log l_3^i \right\} + q_3$$

$$s.t. \qquad c_3^f + c_3^m \le (1+r) b_3$$

3.3 Divorced Agents

In this section, I describe the dynamic problem solved by divorced agents in each part of their life-cycle. I first go through the problem solved by women. The one solved by men will be symmetric. A divorced woman of age 20-39, with full or joint custody of the children, solves the following maximization problem:

$$V_{D,1}^{f}(xb_{1}) = \max_{\left\{c_{1}^{f}, l_{1}^{f}, l_{1}^{f}, h_{1}^{f}, b_{2}^{f}\right\}} \log c_{1}^{f} + \log c_{1}^{k} + \alpha_{l} \log l_{1}^{f} + \alpha_{tk}^{f} \log \left(t_{1}^{f} + \hat{t}_{1}^{m}\right)$$

$$+ \sum_{t=2,3} \beta^{t-1} E\left\{V_{D,t}^{f}\left(b_{t}^{f}\right)\right\}$$

$$s.t. \qquad c_{1}^{f} + c_{1}^{k} \leq w_{1}^{f} h_{1}^{f} + (1+r) x b_{1}^{f} - b_{2}^{f} + a l_{1}$$

$$c_{1}^{k} + c_{1}^{f} \geq a l_{1}$$

$$t_{1}^{f} \geq \underline{t}_{1}^{f}$$

$$t_{1}^{f} + l_{1}^{f} + h_{1}^{f} = 1$$

where xb_1 is fraction of assets inherited from the marriage and $x \in [0,1]$ is the property division rule set by the law. They choose consumption, leisure, and child care time in a non-cooperative fashion. Moreover, they receive alimony and child support transfers al_1 from the ex-husband. I assume that the total amount of household's consumption should not be lower than the alimony and child support transfer¹⁰. The amount of time to spend in child care has a strictly positive lower bound. This is to capture the time constraint related to the custody. In summary, mothers who have full or joint custody, provide consumption for their children, and are supposed to spend at least some time $\underline{t}_1^{f_{11}}$ in child care. They take as given the child care time choice of the father¹². If the mother does not have custody or there are no children in the household at time of divorce, she will not receive any utility from chid's consumption, child care time. She may receive a transfer al_1 which will only reflect the alimony payment.

The problem solved by divorced women of age 40-59 differs from the one above in the child custody aspect. As no children are in middle age households, divorced

¹⁰A consequence of this assumption is that these transfers cannot be allocated to savings.

¹¹In case of joint custody $\underline{t}_1^f = 0$.

 $^{^{12}}$ For computational simplicity, I assume that child's consumption is a private good at time of divorce.

agents do not receive any utility from neither child's consumption nor child care time. The dynamic program solved by a divorced woman is the following:

$$V_{D,2}^{f}(b_{2}) = \max_{\left\{c_{2}^{f}, l_{2}^{f}, h_{2}^{f}, b_{3}^{f}\right\}} \log c_{2}^{f} + \alpha_{l} \log l_{2}^{f}$$

$$+ \sum_{t=3} \beta^{t-1} E\left\{V_{D,t}^{f}\left(b_{t}^{f}\right)\right\}$$

$$s.t. \qquad c_{2}^{f} \leq w_{2}^{f} h_{1}^{f} + (1+r) b_{2}^{f} - b_{3}^{f} + al_{2}$$

$$c_{2}^{f} \geq al_{2}$$

$$l_{2}^{f} + h_{2}^{f} = 1$$

In the third and last part of their life, the problem is the following:

$$V_{D,3}^{f}(b_3) = \max_{\left\{c_3^f, l_3^f, h_3^f\right\}} \log c_3^f + \alpha_l \log l_3^f$$

$$s.t. \qquad c_3^f \le (1+r) b_3^f + al_3$$

$$c_3^f \ge al_3$$

3.4 Equilibrium

Given wage rates $\left\{w_t^f, w_t^m\right\}_{t=0,\dots,T}$, risk-free return from assets r and initial assets $b_1=0$, an equilibrium for this economy is: a set of decision rules of married agents for consumption $\left\{\hat{c}_t^f(b_t,q_t),\hat{c}_t^m(b_t,q_t)\right\}_{t=0,\dots,T}$, leisure $\left\{\hat{l}_t^f(b_t,q_t),\hat{l}_t^m(b_t,q_t)\right\}_{t=0,\dots,T}$, hours worked in the market $\left\{\hat{h}_t^f(b_t,q_t),\hat{h}_t^m(b_t,q_t)\right\}_{t=0,1,\dots,T}$, child-care time $\left\{\hat{t}_t^f(b_t,q_t),\hat{t}_t^m(b_t,q_t)\right\}_{t=0,\dots,T}$, investment in risk-free assets $\left\{\hat{b}_{t+1}(b_t,q_t)\right\}_{t=0,\dots,T}$; a set of decision rules of divorced

agent i=f,m, with $j\neq i,$ for consumption $\left\{\hat{c}_t^i(b_t^i,\hat{t}_t^j)\right\}_{t=0,\dots,T},$ leisure $\left\{\hat{l}_t^i(b_t^i,\hat{t}_t^j)\right\}_{t=0,\dots,T},$ hours worked in the market $\left\{\hat{h}_t^i(b_t^i,\hat{t}_t^j)\right\}_{t=0,\dots,T},$ child-care time $\left\{\hat{t}_t^i(b_t^i,\hat{t}_t^j)\right\}_{t=0,\dots,T},$ investment in risk-free assets $\left\{\hat{b}_{t+1}^i(b_t^i,\hat{t}_t^j)\right\}_{t=0,\dots,T}$ such that agents maximize, $\hat{b}_{T+1}(b_T,q_T)=0$ and $\hat{b}_{T+1}^i(b_T^i,\hat{t}_T^j)=0 \ \forall i,j=f,m.$

4 Quantitative Analysis

This section proceeds as follows. In Section 4.1 I discuss the calibration which consists of two stages. First, some parameters are assigned numerical values from the data. Second, the remaining parameters are calibrated to match the age-specific divorce rate, average time spent in the market and with children by married agents in the U.S. in 1970 (or 1968 when available). The quantitative importance of the mechanism built into the model can be assessed by its ability to generate an increase in divorce rate as displayed in Figure (2). In Section 4.2, I use the changes in property division, child custody, child support and alimony transfers, to assess their quantitative contribution in explaining the rise in age-specific divorce rate (and hence aggregate divorce rate). In Section 4.3 I decompose the increase in divorce rate to analyze which group of agents contributed to its increase the most. The decomposition is based on presence and number of children, and on initial wealth. In Section 4.4 I study the implications of the legal changes in time allocation choices. Finally, in Section ??, I test the effect of a change to unilateral decision to divorce.

4.1 Calibration

The first stage of the calibration strategy is to assign values to some parameters using some a-priori information. The model period is twenty-five years for the young age group, fifteen years for the two other groups. Agents are born married at age 20. The length of the model life is T=3, the interest rate is r=0.04, and the subjective period discount factor is $\beta=(1/(1+r))^{25}$ or $\beta=(1/(1+r))^{15}$. Initial distribution of assets matches the distribution of assets of married agents of age 20-44 in 1962

in the U.S. According to Bossons (1973), 93% of these households owned assets for a value lower than $$15,000^{13}$; 4.7% had assets for a value between 15 and \$30,000; 1.7% owned assets valued between 30 and \$60,000; the remaining 0.6% had assets valued more than \$60,000.

For men and women of age 20 to 59, I use a wage distribution computed from IPUMS 1968. The average wage rate of a married man of age 20-44 is such that his total labor earnings are equal to 1. I assume that all married women work in the market. Alimony and child support transfers are computed using IPUMS Current Population Survey data from 1968^{14} as a percentage of total labor earnings of young married men. The property division rule is set according to Weitzman (1985), and x = 91% implies that, at time of divorce, wives receive 91% of the assets accumulated throughout marriage. The distribution of married couples with and without children matches the data for the U.S. in 1968. Also, in case of divorce, mothers are the only custodians of the children.

The remaining parameters are those that characterized the stochastic process of the match quality, i.e.:

- ullet average μ
- variance σ_{ϵ}^2
- persistence ρ

the weights on the utility function, i.e.:

- men leisure α_l^m
- women leisure α_l^f
- child care time for fathers α_{tk}^m
- child care time for mothers α^f_{tk}

 $[\]overline{^{13}1962}$ U.S. dollars.

¹⁴Only data on realized transfers are available. It is not possible to infer from the available variables whether a divorced woman/man was/was not supposed to receive the transfer.

and the Pareto weight γ_i .

I build a measure of the distance between statistics in the model and the corresponding statistics in the U.S. data. The procedure targets the following statistics:

- (i) divorce rates for the following age groups:
 - \cdot 20 to 44;
 - · 45 to 59;
 - \cdot 60 to 75;
- (ii) average fraction of time worked by young (20-44) divorced women;
- (iii) average fraction of time worked by young (20-44) married men;
- (vi) average fraction of time worked by young (20-44) married women;
- (v) average fraction of time spent by young fathers in child care;
- (vi) average fraction of time spent by young mothers in child care;

I then choose each of the parameters simultaneously to minimize this function. Table 5 shows the value of the calibrated parameters.

Table 5: Calibrated Parameters

Para	ameter	Moment Matched in the Data	
$\overline{\mu}$	0.45	Time Worked, divorced women 20-44	0.29
α_l^m	0.95	Time Worked, married men 20-44	0.33
α_l^f	0.95	Time Worked, married men 20-44	0.06
α_{tk}^m	0.06	Child Care Time, married men 20-44	0.06
α_{tk}^f	0.99	Child Care Time, married women 20-44	0.27

The model is able to match the calibration targets in terms of moments summarized in table 6, but the divorce rate for the eldest age group. The main reasons of

reason of this is that the income level of divorced men of age 60+ is always too low to get them to agree on divorcing and facing the possibility of paying alimony to the wives.

Table 6: Calibrated Parameters - Contd.

	Benchmark	Data
Overall	14	14.9
Divorce rate age 20-44	21.0	21.0
Divorce rate age 45-59	6.0	6.0
Divorce rate age 60+	0.0	1.8
λ	0.22	
σ_{ϵ}^2	0.31	
ρ	0.45	

4.2 Baseline Experiment

The main quantitative implications of the model are with respect to the change in the divorce rates from 1970 to 1980. In this baseline experiment I *simultaneously* make the following changes:

- (i) property division x decreases from 90% to 57% to wives;
- (ii) distribution of custody changes from 100% of the cases to mothers to 90.2% to mothers; 3.2% to fathers; and, 6.6% to both (joint custody);
- (iv) changes in alimony, child support transfers, and probability of receiving the transfers are as in tables 2 and 3.

All of these changes in the parameters of the models are made to assess the impact of the legal changes that occurred from the end of the Sixties to the beginning of the Seventies.

The results are summarized in the following.

Table 7: Results

		1970	1980	Change
20-44				
	Data	21	31	10
	Model	21	25	4
45-59				
	Data	6.0	7.0	1.0
	Model	6.0	6.2	0.2
60+	Data Model	1.8 0.0	2.0 0.0	0.2 0.0
Overall	Data Model	14.9 14	22.6 16.1	7.7 2.1

The model explains about 40% of the increase in divorce rate of the young couples, about 30% of the increase in divorce rate of middle age couples. What is driving the results? The young age group is the one that contributes the most to the increase in the divorce rate. As we have seen, it is also the group that was affected the most from the change in the law. The following section helps in understanding who among the youngs divorced more.

4.3 Decomposing the Forces

Who does contribute the most (or the least) to the increase of the divorce rate? In this section, I show how the model performs in terms of divorce rate by number of children, and by educational level (or initial wealth) of young married couples.

The divorce rates by number of children and educational level are my computation using the number of divorces by categories provided by the Vital Statistics of the U.S.

Table ?? shows that the model does not a good job in matching the divorce rates of couples with and without children in 1968. But, as in the data, the increase in divorce rate is higher for couples with children than for those without children.

Table 8: Divorce Rate by Number of Children

		1970	1980	Change
With Children				
	Data	9.7	14	4.3
	Model	11	14	3
Without Children				
	Data	7.1	4.7	-2.4
	Model	10	11	1

The model performs better in matching the divorce rate of married couples with initial assets that are in the 90th percentile of the distribution (see Bossons (1973)). It is not the case for the case of married couples with of high level initial wealth¹⁵.

¹⁵As the yearly number of divorces of couples by value of assets owned is not available, I approximate this measure with the ratio of the number of divorced females with/without college degree and the number of married females with/without college degree of age 39, 59. The source is IPUMS Current Population Survey, 1968 and 1980. There are no observations available for divorced of age 79.

Table 9: Divorce Rate by Education Level

		1970	1980	Change
Less than College				
	Data	8.8	14.6	5.8
	Model	9	18	9
College and more				
	Data	9.5	12.2	2.7
	Model	12	7	-5

4.4 Implications on Time Allocations

The exercise predicts some changes in terms of the time allocation choices. These changes mostly regard young divorced women for whom the comparative statics exercise predicts an 18% increase in time allocated to the market activity, and a 26% decrease in time spent with children. Moreover, middle age women increase increase the time spent in the market by 13%. Time spent in child care decreases for both by about 24%. Time in the market does not change for married women, but it decreases for young married men by 24%.

Table 10: Market Time Allocation. Source: Survey of Time Use for 1965 and 1985

5 Conclusions

At the end of 1960s, divorce law underwent major changes. This paper assesses the quantitative impact of changes in divorce settlements on the divorce rate. Unlike the existing empirical literature, I do not consider the change to unilateral divorce, and show that changes in the divorce settlements contribute to a substantial increase in divorce rate. In particular, together changes in child custody assignments, alimony transfers and division of property account for 40% of the increase in divorce rate of couples in the age group 20-44, and for 30% of the increase in divorce rate of couples of age 45 to 59. Moreover, the relative changes in age-specific divorce rate predicted by the model are consistent with the data.

6 Appendix

6.1 Numerical solution and Algorithm

I solve the model by backward induction. Consider any arbitrary period. Each couple enters the period with a stock of assets, and a certain match quality. They draw a new match quality, and choose allocations for the case they remain married, and the case they get divorced. For each agent, I evaluate the level of utility associated with the two marital status. The level of utility conditional on marital status is computed by checking all of the possible alternatives for consumption, labor supply, time to spend with children, and saving. For each possible choice, I select the one that yields the highest level of utility. If at least one of the spouses prefers to stay married, then they remain married; if both of them prefers to divorce, they will divorce¹⁶.

The presence of a discrete choice (decision to divorce) and several continuous decision variables like labor supply, time spent with children and saving implies that the value function of the married agents is not necessarily concave or differentiable. To solve the problem I discretize the continuous choice variables. The grid for time allocation decisions includes thirty equally spaced points in the interval [0, 1]. Wealth is described by a thirty point uniform grid in the interval [0, 8].

The solution of the model is characterized by policy functions. For every state of the world, the policy functions returns the optimal choices for marital status, consumption, allocation of time between the market and the children, and saving. The policy functions are used to simulate the shock histories for 10,000 married couples. Using the simulated histories and the optimal decision rules, I compute the target moments for the model economy. I proceed by minimizing the sum of the square difference between the target and the simulated moments. The procedure is called Downhill Simplex, and does not require the calculation of derivatives.

¹⁶This is the case of consensual divorce. In case of unilateral divorce, the will of one party is sufficient to start the process of the decree.

6.2 Data

Alimony and child support payments¹⁷ are from the Current Population Survey of the U.S. of 1968 (see Miriam King and Sobek (2004)). The sample includes divorced and separated females with children present in the household, of age 20 to 39, that are in the labor force, and who received the transfers.

Data on custody are from the National Longitudinal Survey High School Class 1972 (Fifth Follow-up). The sample includes all mothers who have been married and divorced at least once. All of them are in the age group 30 to 40. In questions 67 and 68 of the survey (variable FI167 and FI168), respondents are asked to provide information about child custody and visitation agreement.

The percentage of properties allocated to wife after divorce is also computed using data from the National Longitudinal Survey High School Class 1972 (Fifth Follow-up). More precisely, I analyze the answers given in question 62A (var. FI62A) and question 62B (var. FI162B). For each respondent, those variables provide the (intervalled) amount of properties received by themselves and by the spouse.

Table 13 reports the age-specific divorce rates for the states for which the data were available in both 1970 and 1980.

¹⁷All of the figures are deflated using the Consumer Price Index (1982-1984=100).
